## Recent Demographic Trends in France: The Number of Marriages Continues to Decrease

## I. General trends and population age structure

## A narrowing gap between birth and death rates

On 1 January 2014, the population of France was close to 66 million ( 65.8 million), including 2.1 million in the overseas departments excluding Mayotte, and 0.2 million in Mayotte (Bellamy and Beaumel, 2014).

Over the course of 2013, the population increased by 300,000, of which 240,000 in metropolitan France (mainland France and Corsica), where the growth rate was $0.42 \%{ }^{(1)}$ This is a decrease with respect to 2012 , when it was estimated at $0.49 \%$ (Appendix Table A.1). ${ }^{(2)}$ This growth was due mainly to natural increase ( 3.4 per 1,000) , which is the difference between the birth rate of 12.2 per 1,000 and the death rate of 8.8 per 1,000 . The gap between these two rates has been progressively narrowing, from 4.6 per 1,000 in 2006 to 3.4 per 1,000 in 2013 (Appendix Table A.1).

## The rate of natural increase remains one of the highest in the European Union

The rate of natural increase in France is among the highest in the European Union (Figure 1). In 2012, just half of the countries in the EU had a positive rate. Ireland topped the rankings thanks to its high fertility and a younger age

[^0]Figure 1. Annual rates of natural increase, 2001-2012, European Union (per 1,000)

structure than other countries. In 2010, the median age of the Irish population was 34.3 years, versus 44.2 years in Germany; the proportion of individuals aged 65 or older in the two countries was $11 \%$ and $20.7 \%$, respectively (Mazuy et al., 2013).

Rates of natural increase vary from a maximum of 9.5 per 1,000 in Ireland to a minimum of -5.5 per 1,000 in Bulgaria. The rate is between 5.2 and 2.1 per 1,000 in six countries (Cyprus, Luxembourg, France, the United Kingdom, Sweden, and the Netherlands) and between 1.7 and 0.6 per 1,000 in seven countries (Belgium, Malta, Finland, Slovenia, Spain, Denmark, and Slovakia). The other 14 countries have zero or negative rates. Seven countries have a rate between 0 and -1.7 per 1,000 (Poland, Czech Republic, Austria, Estonia, Italy, Greece, and Portugal). Finally, the remaining seven countries have a rate between -2.3 and -5.5 per 1,000 (Croatia, ${ }^{(3)}$ Germany, Romania, Lithuania, Hungary, Latvia, and Bulgaria).

Net migration rates in certain countries are low or even negative, notably in the countries of central and eastern Europe, but also in Spain, Greece, and

[^1]Ireland (Figure 2). This is speeding up population decline in certain countries, such as Bulgaria and Latvia, for example, which have negative rates of both natural increase and net migration, and which lost more than $10 \%$ of their respective populations between 1980 and 2010 (Avdeev et al., 2011). In situations of falling natural growth rates, the migratory component, when positive, has a stronger relative impact on levels of growth and on the ongoing processes of population ageing (Ambrosetti and Giudici, 2013).

In the countries of southern, central, and eastern Europe, the population under age 20 has fallen drastically, decreasing by more than $30 \%$, for example, between 1980 and 2008 in Bulgaria, Latvia, the Czech Republic, and Romania,

Figure 2. Annual rates of net migration, 2001-2012, European Union (per 1,000)

and by $35 \%$ in Italy over the same period. At the same time, the older population has increased to a varying extent (at the top of the age pyramid), due to mortality conditions that diverge across different European countries. In central and eastern Europe and in the Baltic countries, less favourable mortality conditions have slowed the growth of the older population. In Hungary and the Czech Republic, for example, it increased relatively slowly over this period (10\%) due to high mortality.

## Ageing of the French population is set to accelerate

The transformation of the French population pyramid over the last century (1914-2014) reflects the progressive ageing of the population (Figure 3) (Pison, 2014). In 1914 the pyramid was in the shape of a haystack. In 2014 its base is still relatively wide, but the baby-boom generations will strongly accentuate the ageing process in the coming decades. The 1954 population pyramid clearly illustrates the effects of the two World Wars (in particular, the birth deficit) as well as longer-term effects such as the baby boom (the first large cohorts are quite visible at the base of the pyramid). In the near future, the arrival of these large cohorts in the upper age groups (above age 65) and the decrease in the proportion of women of reproductive age in the population will strongly affect crude birth and death rates, as well as the age distribution of the population. In 2014, a quarter of the population is below 20 years old. Another quarter is 60 years old or more, and nearly one person in ten ( $9.2 \%$ ) is aged 75 or older (Appendix Table A.2). The over-60s will make up an increasing proportion of the population in the coming decades, and they could account for $30 \%$ of the total in 2035 (Blanpain and Chardon, 2010).

## II. Statistics on immigration from third countries, based on long-term residence permits

Net migration, which measures the difference between entries and exits of persons to and from French territory over the course of a year, can be decomposed into the entries and exits of French nationals and those of foreigners. Certain citizens of countries outside the European Union are obliged to hold a residence permit to reside in France. This section focuses on recent trends in the entries of citizens of these countries.

## A third of permits are long-term visas equivalent to residence permits

Flows of foreigners ${ }^{(4)}$ arriving legally in France to establish residence in the country can be estimated from statistics on long-term residence permits and long-term visas (valid for one year or more) valid as residence permits. These statistics only concern countries whose nationals require
(4) Born abroad to non-French parents.

Figure 3. Population pyramids in 1914, 1954, and 2014

[^2]Source: Pison, 2014.
a residence permit to live in France, so they exclude migrants from within Europe (i.e. from countries listed in Footnote 5). They are based on data from the system used by the French Ministry of the Interior to track the status of foreigners residing in France (AGDREF) and were compiled at INED (Appendix Table A.3).

To ensure consistency of comparisons over time, the statistics presented below are established for a constant geographical area. They therefore exclude residence permits granted previously to immigrants from countries whose nationals no longer need a residence permit. ${ }^{(5)}$

The residence permits considered here have two important characteristics. First, they are valid for a period of more than one year, so all short-term permits are excluded. Second, among the permits of more than one year granted to a given immigrant, only the first is taken into account, to avoid counting the same person more than once. These methodological choices enable us to focus on permanent migration and to count the inflow of foreigners with long-term migrant status. In other words, migrants who were granted two successive seven-month permits and then left the country, for example, are not counted. Moreover, flows are characterized on the basis of the permits themselves: validity start date, period of validity, and the reason for granting the permit. Two of the permit-holder's characteristics are also taken into account: sex and age at the time the permit was granted. The principal advantage of the AGDREF database is its exhaustive coverage of migrants receiving a long-term permit.

Additional figures are also published by the Ministry of the Interior, whose statistics include all permits granted (including short-term permits), and by INSEE, which estimates migrants' actual date of arrival in France and duration of stay. The latter estimates thus correspond more closely to international standards, notably those of Eurostat, which recommends that estimates be based on the actual duration of stay, rather than on the period of validity of the residence permit. To produce its estimates, INSEE uses a census question on year of arrival in France. However, flows estimated from census data are also based on a constant geographical area, and are comparable to those calculated using the AGDREF database (Brutel, 2014; Arbel and Costemalle, 2015).

Table 1 presents the flows, between 2007 and 2012, of migrants who were granted a residence permit with a duration of one year or more for the first time. The number of permits granted to foreigners remains very stable around a mean of approximately 182,000 per year. In the last few years, there has been a slight downward tendency in this figure. Nearly $90 \%$ of these first permits are valid for less than 10 years.

[^3]Table 1. Number of first permits of one year or more granted to nationals of third countries (constant geographical area) by first year of validity and period of validity

| Period of validity | 2007 | 2008 | 2009 | 2010 | 2011 | 2012 |
| :--- | ---: | ---: | ---: | ---: | ---: | :---: |

Residence permits are issued in France, whereas long-term visas valid as residence permits are issued in French consulates abroad. The AGDREF only takes into account holders of long-term visas who present themselves at the prefecture on arrival in France. This is an obligatory requirement for migrants wishing to live in France for more than one year. Since 2010, long-term visas valid as residence permits have represented more than $36 \%$ of all permits granted.

## A majority of women and of adults below age 35

The distribution of permits granted in 2012 by age and sex reveals the concentration of migrants in the 20-35 age group (Figure 4). More women than men were granted residence permits, and their mean age was slightly higher.

The age distribution of adult permit holders remained very stable over the period (Table 2). The proportion of minors, who are generally not legally required to apply for a permit, has been decreasing steadily since 2005. In

Figure 4. Distribution of permits granted in 2012 by age and sex

2012, 17,509 permits were granted to minors. Among adults, the age distribution was highly concentrated in the youngest age group: two thirds of permits were granted to persons aged 18-34.

Table 2. Distribution of holders of a first residence permit of one year or more by age group and first year of validity (\%)

| Age group | 2007 | 2008 | 2009 | 2010 | 2011 | 2012 |

African nationals represent a large majority of recipients of a first residence permit, although their proportion has decreased slightly since 2002, and the proportion of immigrants from other continents has increased (Table 4). The principal countries of origin of recipients were Algeria ( 24,460 permits granted in 2012), Morocco ( 21,616 permits), Tunisia ( 11,374 permits), and Turkey (6,626 permits).

Table 4. Distribution of holders of a first residence permit of one year or more by continent of origin and first year of validity (\%)

## Half of permits are granted for family reasons,

 a quarter for educational reasonsThe proportion of permits granted for family reasons seems to have strongly declined over the period considered (Table 5), returning to the level of the early 2000s. Analysis of recent changes is difficult, however, given the large increase in permits granted for unspecified reasons. Half of permits were granted for family reasons, and a quarter for educational reasons. In 2012, 9,753 permits were granted for work-related reasons (including 915 for seasonal work) and 17,338 for humanitarian reasons.

Table 5. Distribution of holders of a first residence permit of one year or more by reason for admission and first year of validity (\%)

## III. Births, birth rates and women's fertility

## A downward tendency since 2010

The estimated number of births in 2013 is 810,000 for the whole of France and 780,000 for the metropolitan départements. There were fewer births in 2013 than in 2012, when 821,000 births were registered, including 790,000 in metropolitan France (Appendix Table A.1). This decrease is due to the combination of a slight decrease in women's fertility, which fell from 2.01 children per woman in 2012 to 1.99 in 2013 ( 1.99 in 2012 and 1.97 in 2013 for metropolitan France), and a $0.7 \%$ decrease in the number of women of reproductive age over the year 2013 (Bellamy and Beaumel, 2014). The number of births registered in 2012 is close to that of 2005.

The crude birth rate decreased from 12.4 to 12.2 births per 1,000 inhabitants, a drop of $1.2 \%$ between 2012 and 2013. The number of births is gradually decreasing even as the total population continues to increase; the result is a decrease in the crude birth rate.

## Moderate continuation of the trend towards later childbearing

Only the fertility of women aged 35 or older increased slightly between 2012 and 2013, reaching 338 births per 1,000 women at ages $35-39$, and 87 births per 1,000 women aged 40 or above (versus 332 and 84, respectively, in 2012) (Table 6).

The fertility rates of all other age groups decreased. The sharpest fall was at ages $20-24$, followed by ages 25-29. The shift toward later fertility continues.

Looking at changes since 1960, it can be seen that modal values fell sharply from the 1960s to the 1980s, as did fertility rates at later ages (Figure 5). In 1990,

Table 6. Fertility by age group since 2008 (per 1,000 women)

| Age reached in the year | Sum of age-specific rates |  |  |  |  |  | Absolute variation* |  |  |  |  |

Figure 5. Age-specific fertility rates in 1960, 1970, 1980, 1990, 2000, 2010, and 2013 (per 1,000 women)

Source: Authors' calculations based on birth records, adjusted according to the size of the female population at each age.
the curve of age-specific fertility rates began shifting to the right. This pattern reflects progressive increases in age at childbirth. Since the 1990s, the year-onyear differences in age-specific fertility rates have decreased; the tendency towards later childbearing has continued, but at a more moderate pace. After decreasing in the 1960s and 1970s, mean age at childbearing (calculated using age-specific rates) began to increase in the late 1970s, and continued to do so over subsequent years. Women had children at a mean age of 27.6 years in 1960, 26.8 years in 1980, 29.4 years in 2000, and 30 years in 2010.

This recent pattern of change is due mainly to the widespread diffusion of contraception, which has offered women and couples greater control over the timing of childbirth. Age at first childbirth (which has been above 28 since 2010, see Appendix Table A.4), intervals between births, and number of children (notably with the diffusion of the two-child norm) are no longer left to chance.

## Fertility remains high

According to current estimates, fertility levels in France continued to rank among Europe's highest in 2013. In 2012, France was in third place, behind Ireland and Iceland (Appendix Table A.6). Fertility remained very low in the countries of southern and eastern Europe. Germany, Cyprus, Spain, Greece, Hungary, Poland, Portugal, and Slovakia recorded the lowest fertility in 2012, with total fertility rates below 1.4 children per woman. Estimates of completed fertility are also very low for these countries (between 1.4 and 1.6 children per woman for the cohorts born in the mid-1970s). ${ }^{(6)}$ In France, the mean number of children has stabilized at two children per woman for all the cohorts born in the late 1960s and 1970s (Appendix Table A.5). Mean age at childbearing has increased less in certain European countries than in France. In some countries, however, notably in eastern Europe, fertility remains relatively early. This is the case in Bulgaria, Slovakia, and Lithuania, where the mean age is below 27 (Appendix Table A.7). The countries with the highest mean age at childbearing are Spain, Ireland, and Italy, where it is above 31 years.

## IV. Induced abortion

## Stable rates and concentration of demand at ages 20-24

According to data based on medical statistics, the number of induced abortions remained stable in 2012 (Vilain et al., 2014). A total of 219,200 abortions ${ }^{(7)}$ were registered in 2012, of which 207,120 in metropolitan France (Appendix

[^4]Table A.8). The abortion rate is stable, at 14.5 induced abortions per 1,000 women aged 15-49. Abortions have become less frequent among minors and women below age 20, and are now concentrated at ages 20-24. In 2012, abortions performed at ages 20-29 accounted for nearly half of the total abortion rate (48\%), those performed at ages 30-39 for $30 \%$, those before age 20 for $15 \%$, and those after age 40 for $7 \%$ (according to rates calculated from data in the PMSI medical statistics database). The mean age at abortion was 27.6 years in 2012. ${ }^{(8)}$

## Fewer women seek induced abortions, but repeat abortions are more frequent

Data from abortion notifications (Box) indicate the number of previous induced abortions and the date of the last abortion. Analysis of the data reveals that repeat abortions have become more frequent since the late 1990s. The stability of abortion rates thus results from two opposing trends: a lower lifetime

## Statistics based on abortion notifications and other sources of statistical data

For each induced abortion, physicians fill in an anonymous abortion notification. These notifications are sent to regional health agencies and centralized by the Ministry of Health, which makes them available to INED and INSERM through anonymous databases. Since legalization of abortion by the Veil Act in 1975, INED is required to publish annual statistics on induced abortions. There have been a series of different versions of the notifications since 1975, and the resulting data are not strictly homogeneous through time (Mazuy et al., 2014). Beyond 2015, it is not known if the system for recording data from abortion notifications will continue, since medical statistics can also be used to analyse induced abortions. However, hospital statistics provide less detailed information than abortion notifications or dedicated surveys. These data could potentially be expanded with various medical variables (such as the number of previous abortions, date of last abortion, number of previous births). General population surveys underestimate induced abortions and cannot be used as a primary source to assess changes in abortion rates over time, but they offer much more detailed information on the life context of women who have abortions. Finally, analyses could also be based on dedicated surveys of women who have had an induced abortion over the course of a reference period. The last survey of this type was carried out in 2007 with an initial sample of 200 health facilities, 1,300 practitioners, and 13,000 women. The survey was spread over one to six months depending on the type of abortion, the region, and the women's age (Vilain et al., 2011; Collet et al., 2012). A survey of healthcare facilities aimed at studying waiting times and difficulties encountered by women seeking an abortion was commissioned by the Minister of Health in March 2014.

[^5]probability of having an induced abortion, but an increase in the probability, among women who have an abortion, that they will do so more than once. Moreover, frequency of repeat abortion increases with decreasing age at first abortion: $48 \%$ of women who have a first abortion before age 26 subsequently have repeat abortions, versus $18 \%$ of those who have their first induced abortion after this age (Mazuy et al., 2014).

## V. Marriages, civil partnerships (PACS), and divorces

## A renewed downtrend in marriages

After a slight rise in 2012, the already long-established downtrend in marriages continued in 2013, with the number of marriages reaching a historical low of 231,000. From 1900 until the mid 1960s, the annual number of marriages oscillated around 300,000, with highly marked variations, notably linked to the two World Wars and to their knock-on effects over the short, medium, and long term (Figure 6A). The cohorts born in the 1950s, who reached adulthood in the 1970s, made up a numerically large "reserve" of marriageable men and women. A peak in marriages was recorded in the early 1970s, with more than 410,000 marriages in the year 1972. Up until that year, decreasing age at marriage had reinforced this effect. Beginning in 1972, the number of marriages began to decrease. In the 1990s, the pattern of change was more erratic, but the downtrend in marriages resumed in the early 2000s. In parallel, civil partnerships (pacte civil de solidarité, PACS) were introduced on 15 November 1999 and became increasingly popular. Although the PACS did not completely substitute for marriage, it very probably contributed to the decline in the annual number of marriages.

For some couples, civil partnership is seen as an alternative to marriage, while for others it may constitute a "trial marriage" (Rault, 2009). The PACS is thus contributing both to the drop in the number of marriages and to their postponement.

The slight increase in marriages in 2012 (Figure 6B) could be linked to the 2011 tax reform: since 1 January 2011, married persons (and those in civil partnerships) no longer fill in three income tax declarations (as two singles and then as one couple) in the year of their marriage (or PACS), but instead must choose between one joint declaration or two separate declarations for the full year (i.e. their income tax is now calculated over the entire year and no longer separately for the periods before and after the marriage or PACS). This reform may have had a marked dissuasive effect in 2011, the first year of its application. The 2012 increase should thus be viewed more as a catch-up effect following the drop in marriages in 2011, with the additional marriages in 2012 being postponed weddings initially planned for 2011.

## The number of first marriages continues to decrease

The decrease in first marriages is measured by the sum of rates (total first marriage rate) or the overall probability of first marriage. Between 1972 and 2012, the total first marriage rate fell from 91.7 to 46.6 first marriages per 100 men, and from 94.8 to 47.5 first marriages per 100 women. Probability data show a strong decrease in the proportion of marriages between never-
married persons up to age 50: it fell from 90 first marriages per 100 nevermarried men in 1972 to 53.5 in 2012, and from 93.4 first marriages per 100 never-married women to 56.3 for the same years (Beaumel and Bellamy, 2014). Women's and men's probabilities of first marriage follow a similar pattern between 1970 and 2012, in terms of both level and intensity, but men marry two years later on average due to the age gap between spouses (Figure 7). In 40 years, mean age at first marriage has increased by more than eight years for both sexes: never-married women married for the first time at a mean age of 22.5 years on average in 1972 and of 31.1 years in 2012 (according to agespecific probabilities); the respective figures for men are 24.6 and 32.8 years. Across cohorts, the delay in first marriages is also pronounced: the mean age was below 23 for women born in the mid-1950s and is above 28 for women born in the 1970s. The respective figures for men are age 25 (for those born in the mid-1950s) and above 30 for those born in the 1970s (Appendix Table A.10).

Figure 7. Age-specific probability of first marriage, women and men, 1972-2012 (per 10,000)

## 7,000 same-sex marriages in 2013

Law no. 2013-404 of 17 May 2013 authorized marriage between two persons of the same sex, and 7,000 same-sex marriages were contracted in that year (Bellamy and Beaumel, 2014). They took place in the second half of 2013, following enactment of the law on 18 May. A peak in such marriages was recorded a little more than 3 months later, in September 2013. Over the same period (second half of 2013), 3,100 same-sex couples entered into a civil partnership (PACS). Thus, around 20,000 men and women officialized their samesex union in the second half of 2013. Married same-sex couples are older, on average, than heterosexual couples: age 50 years for men and 43 for women, versus 37 for men and 34 for women in heterosexual marriages. The age gap between partners is also larger: 5.5 years for women and 8 years for men
(Bellamy and Beaumel, 2014). This age gap is also observed for civil partnerships: in 2009-2010 it was 5 years for women and 7 years for men (Mazuy et al., 2011).

## 168,000 PACS registered in 2013, including 13\% by notaries

Since it came into effect on 15 November 1999, the PACS has been widely adopted throughout French society, with a peak in 2010, when 205,500 PACS were registered. The number of PACS fell to 152,000 in 2011, the year of the tax reform, but increased again in 2012 and 2013 (Table 7, Figure 6B). In 2013, 168,000 PACS were registered, representing more than $40 \%$ of officialized unions (PACS and marriages combined). The PACS has become widespread among heterosexual couples, who account for $96 \%$ of all PACS unions.

* Provisional

Coverage: Whole of France, excluding Mayotte.
Source: Ministry of Justice (unions registered in magistrates' courts and through notaries).

In 2013, 13\% of PACS were registered by a notary. According to a recent study by the Ministry of Justice, couples who register a PACS through a notary are older than those who do so directly at the magistrates' court (Büsch and Timbart, 2014). These couples are perhaps more concerned to ensure mutual protection in case of the death of one of the partners than those who register a PACS at a magistrates' court (the notary can also draw up a will for the couple ${ }^{(9)}$ ).

## Divorces and PACS dissolutions

Over the year 2013, 125,109 divorces were pronounced (Table 8), including 121,849 in metropolitan France (Appendix Table A.9). This is slightly fewer than in 2012, when 128,371 divorces were pronounced. More than half of divorces (direct divorces) are pronounced by mutual consent ( $53.5 \%$ ). The total divorce rate reached 45 divorces per 100 marriages in 2012, a slight decrease with respect to 2011 (Appendix Table A.9).

From a longitudinal point of view, on the basis of probabilities by marriage duration, divorce has increased with successive cohorts. Between the 1970 and

[^6]Table 8. Number of divorces since 2010

2000 cohorts, the overall probability has doubled for a marriage duration of 10 years, and at almost all ages the overall probability has increased across successive cohorts (Figure 8).

The number of PACS dissolutions has been increasing, and surpassed 53,000 in 2013 (Table 9). In nearly four out of ten cases (38\%), the PACS is dissolved because the couple gets married. When PACS are dissolved due to separation, it is almost exclusively by mutual agreement.

## VI. Mortality

The 572,000 deaths in the year 2013 correspond to a crude mortality rate of 8.7 deaths per 1,000 inhabitants ( 8.8 for metropolitan France) (Appendix Table A.1). Life expectancy at birth is provisionally estimated at 78.7 years for males and 85.0 years for females (both for the whole of France and for metropolitan France). These levels of life expectancy represent a gain of slightly more than two months for both sexes with respect to the previous year. Above all, this increase means that the small decrease in female life expectancy at birth between 2011 and 2012 was only a momentary variation due to the timing of the winter flu epidemic, and does not reflect a durable interruption in the trend of decreasing mortality. These figures also mean that the gender gap in mean length of life remained practically stable with respect to 2012, at 6.3 years (Figure 9).

## A renewed increase in life expectancy

Recent changes are consistent with the trends observed over the last 20 years. Since 2003, men's mean length of life has increased by 2.8 years and that of women by 2 years, an annual increase of 0.28 and 0.20 years, respectively (Appendix Table A.11). Improvements were slightly more rapid over the past decade than over the preceding one. Between 1993 and 2003, the mean increase was 0.26 years for males and 0.16 years for females. As men's life expectancy has increased faster than women's over these two decades, the sex difference in mean length of life, which reached a peak of 8.2 years at the beginning of the 1990s, has since been steadily decreasing.

In 2012, although female life expectancy at birth in France (84.8 years) was below that of Switzerland and Spain (84.9 years and 85.5 years, respectively), France remained close to the top of the European ranking (Appendix Table A.12). For males, it was in a less favourable twelfth position (out of a total of 29 countries). Contrary to the situation two decades ago, excess male mortality

Figure 9. Life expectancy at birth (both sexes combined) and difference between male and female life expectancies at birth, 1990-2013

Source: INSEE.
in France, which at the time was among the highest in western Europe, is now in the lower middle of the distribution, with a difference of 6.3 years between the sexes. Mean sex differences in life expectancy are much higher in some other countries - as high as 10 to 11 years in Sweden, Switzerland, and Iceland. For infant mortality, France stands exactly in the middle of the ranking, at 3.5 per 1,000 in 2012 (Appendix Table A.13).

## Rising life expectancy thanks to lower mortality above age 60

The steady increase in mean length of life conceals unequal improvements over time by age and cause of death. Figure 10 shows, for both sexes, how age-specific probabilities of dying changed between the three-year life table of 1990-1992 and that of 2010-2012. The general trend is identical for males and females. The greatest improvements are seen for young people, with probabilities of dying halved up to the ages of 30-35 years. Improvements taper off gradually with increasing age, with a particularly small decrease around the ages of 50-55. There are nevertheless notable differences between the sexes. Male mortality decreased more than female mortality between the ages of 25 and 75 , but a little less above age 75 . The most marked difference between the sexes over this period was in the 45-50 age group, where, again, a larger mortality decrease was observed for men than for women. As we will see below, an examination of causes of death sheds light on these differences.

Decreases in mortality at different ages have unequal effects on changes over time in life expectancy at birth. Child mortality has reached such low levels that any changes now have little effect on life expectancy at birth: between 1990-1992 and 2010-2012, a decrease of 6.7 deaths before age 15 per 1,000

Figure 10. Ratios between the three-year life table of 2010-2012 and that of 1990-1992 for age-specific probabilities of dying (smoothed over 3 years of age), by sex

Source: INSEE, Situation démographique 2012, Table 68.
newborns in 20 years only increased mean length of life by 0.5 years for males and by 0.4 years for females (Figure 11). In contrast, the decrease in mortality at ages 15-45 over the same period played an important role, for males at least, contributing $20 \%$ of the total gain in life expectancy at birth (one out of the total of 5.3 years of life expectancy gained between 1990-1992 and 2010-2012, versus only 0.4 out of 3.7 years, only slightly above $10 \%$, for females). However, the greatest gains are due to improvements at ages $45-80$ in men ( +3 years) and beyond age 65 in women ( +2.6 years).

## Massive decrease in women's cardiovascular diseases

Contributions by cause of death to improvements in life expectancy at birth over the period from 1989-1991 to 2009-2011 ${ }^{(10)}$ vary greatly by age and sex (Table 10). Note, however, that while decreasing male mortality can be attributed to decreases in various pathologies (notably external causes in young adults, cancers around ages 45-75, and diseases of the circulatory system at age 60 and beyond), improvement in females is overwhelmingly due to decreases in cardiovascular diseases (both heart diseases and cerebrovascular diseases) (Appendix Table A.14).

## Infant mortality: a growing contribution of diseases of early infancy

Following a long-term trend, infant mortality from infectious diseases (above all respiratory diseases) continued to decrease steadily between 1990

[^7]Figure 11. Contributions by age group to gains in male and female life expectancy at birth between 1990-1992 and 2010-2012
(5.3 and 3.7 years in total)

Source: Authors' calculations on the basis of INSEE's three-year life tables by sex.
and $2010^{(11)}$ (see also Meslé, 1995). Mortality due to external causes (mainly accidents, at this age) also decreased steadily up until 2008, but seems to have stabilized since, particularly for girls.

The weight of sudden infant death syndrome in infant mortality statistics grew considerably from the mid-1970s and peaked in the late 1980s, before declining very sharply for a few years, and more slowly in subsequent years, thanks to campaigns advising parents not to lay infants on their stomachs (Barbieri, 1998). The mortality rate in the first year of life from this cause decreased from nearly 220 deaths per 100,000 births around 1990 to only 27 per 100,000 in 2010 for the two sexes combined - a spectacular drop of nearly $90 \%$ in twenty years.

[^8]Table 10. Contribution of age groups and causes of death to gains in life expectancy at birth (in years) between 1989-1991 and 2009-2011, by sex

Note: The method used to calculate the contribution of each age group and cause to gains in life expectancy at birth between two periods is the one proposed by Andreev, Shkolnikov and Begun (2002).
Source: Authors' calculations on the basis of INSEE life tables by sex and INSERM data on deaths by cause (CépiDc).

The decline in mortality due to diseases of early infancy, in contrast, was very limited over this period, with a relatively small drop in deaths due to congenital abnormalities and an absence of progress for other causes associated with the perinatal period. Consequently, the contribution of these two groups of causes has increased very rapidly over the last twenty years: while they accounted for $50 \%$ of infant mortality in 1990, they now represent more than $75 \%$. If the recent stagnation of mortality from these diseases specific to early infancy persists, it may slow, or even stop, the long-standing trend of declining infant mortality.

## Mortality at ages 15-24: deaths from external causes predominate

For males, deaths from external causes account for most deaths at these ages: in 2010, more than three quarters of the standardized mortality rate in this age range could be attributed to this cause (versus roughly half for women). Road accidents and suicide are the principal causes for both sexes (Appendix

Table A.15). Mortality due to traffic accidents decreased between 1990 and 2010, and particularly after 1999, but trends in mortality by suicide and other external causes have been less favourable. Since 2005, mortality due to these causes seems to have stabilized, and suicide has even recently risen slightly among women.

Change in mortality for the other major categories of causes has not been much more favourable, which explains this age group's particularly small contribution to progress in life expectancy between 1990 and 2010 ( 0.34 years out of a total gain of 5.4 years in men, 0.12 years out of 3.8 years in women). Mortality from infectious diseases is a noteworthy exception: it fell sharply until 1998-2000 thanks to better control of the HIV-AIDS epidemic from the early 1990s.

## Mortality at ages 25-44: contrasting trends in the two sexes

Certain characteristics of the preceding age group are also found among persons aged 25-44. In this age group, the pattern of deaths by infectious disease due to the evolution of HIV-AIDS mortality was just as remarkable as in the younger age group, with both a strong increase up until 1995 and a sharp drop after that year. Whereas at the peak of the epidemic infections were the third-leading cause of mortality after deaths from external causes and cancers, in 2010 they were the least frequent cause.

As in younger people, mortality due to external causes, which was the leading cause of death before 1990, has been steadily declining ever since. The decrease since that time (and especially since 2000) has been very rapid for traffic accidents, with a $57 \%$ drop in the standardized rate for men and a $72 \%$ drop for women between 1990 and 2000. For other external causes in men, however, this downtrend was interrupted from 2003-2004 onward. External causes are still responsible for the majority of male deaths at these ages, representing $51 \%$ of the total standardized rate, versus $26 \%$ for women.

In women of these ages, cancer was the leading cause of death in 2010 (Appendix Table A.15). Twenty years earlier, the standardized mortality rate for cancer was one third higher in men ( 40 per 100,000 versus 30 per 100,000 in women). Due to sustained decreases up until the second half of the 2000s in men, the standardized rate is currently very similar for both sexes, at around 22 per 100,000. This situation results in part from contrasting trends in lung cancer: men's standardized mortality rate from this cause decreased by half in 20 years, whereas it increased in women until around 2005. It also results from rapid falls in cancers of the upper aerodigestive tract (lips, mouth, and pharynx) and the œsophagus thanks to lower alcohol consumption, which have primarily benefited men as the incidence of these pathologies has always been much lower in women. In contrast, breast cancer, the leading cancer in women in terms of mortality, has decreased very slowly.

## Mortality at ages 45-64: cancer strongly predominates

More than at all other ages, cancers constitute the leading cause of mortality at ages 45-64: in 2010, they represented, respectively, $47 \%$ and $56 \%$ of male and female standardized mortality rates in this age range, with highly marked contrasts between the sexes by site.

The most lethal cancers in men (in order of frequency) are those of the lung; the upper aerodigestive tract; the intestine, the colon, and the rectum; the oesophagus; the blood-forming organs; the stomach; and the prostate. In women they are: the breast; the lung; the intestine, colon, and rectum; the uterus; the blood-forming organs; and, to a lesser extent, the upper aerodigestive tract, the stomach, and the oesophagus (Figure 12). There is a very marked contrast between the sexes: for men, deaths from almost all types of cancer decreased over the observed period, while for women, apart from slight decreases in deaths from cancers of the breast and the blood-forming organs, they remained stable or increased. The increase in lung cancer was very pronounced in women, with a standardized rate that more than doubled between 1990 and 2010; this cancer seems to be on the verge of becoming the leading cause of cancer death at ages 45-64. These different trends in men and women are

Figure 12. Standardized mortality rates at ages 45-64 for the most lethal cancers by sex, from 1989-1991 to 2009-2011
(three-calendar-year moving average)

largely explained by differences in smoking behaviours (decreasing consumption among men since the 1970s, regular increases among women, particularly at ages 45-64). ${ }^{(12)}$

Cardiovascular diseases are the second most frequent cause of death at these ages, far behind cancers, with a standardized rate that continues to decline, due to factors including changes in behaviour (notably smoking), decreases in infectious diseases which are risk factors for heart diseases, and medical advances, which have led to considerable improvements in the prevention and treatment of diseases of the circulatory system (Appendix Table A.15).

Mortality from other causes has evolved less favourably, as the downtrend has halted for almost all categories since the early 2000s. However, as these causes account for a much smaller proportion of general mortality, this age group contributed positively to gains in life expectancy between 1990 and 2010, particularly for men (Table 10).

## Mortality at ages 65-79:

## a large drop due to a decline in cardiovascular diseases

Mortality decreased considerably over the period in this age group, which accounts for nearly a third of the years of life gained between 1990 and 2010. These improvements are predominantly due to control of cardiovascular diseases ( $50 \%$ of total gain in men and $62 \%$ in women) and notably ischaemic heart diseases, thanks to improvements in prevention, treatment, and surgery, associated with decreasing tobacco consumption in men.

Decreasing cancer mortality also played an important role in men: it was responsible for a quarter of years of life gained by men, versus only a sixth in women. Whereas the standardized rates for these two groups of causes of death were similar until the end of the 1980s, mortality from cardiovascular diseases has decreased by $50 \%$ in twenty years, versus $15 \%$ and $25 \%$ for male and female cancer mortality.

The ranking of cancers by site in this age group is slightly different than in the preceding one. In men, lung cancer is the leading cause of death, but it is followed by cancers of the colon and rectum, the prostate, the blood-forming organs, and, at a much lower level, the œesophagus, the stomach, and the upper aerodigestive tract. The decreasing trend in mortality for all cancers in men beginning in 1990 seems to have been interrupted in recent years, with two exceptions: blood cancer (cancer of the blood-forming organs), mortality from which has stabilized since the early 1980s, and prostate cancer, which has continued to decrease, with a standardized rate in 2011 at half its 1990 level. For women, the ranking is very similar to the one for ages 45-64: cancer of the breast, followed by the lung, the colon and rectum, the blood-forming

[^9]organs, and, further behind, the stomach, the œsophagus, and the upper aerodigestive tract. Mortality from all cancers combined has levelled off since the early 2000s, except for lung cancer, which has been in constant increase due to the high prevalence of smoking in these generations, and stomach cancer, which continues to decrease.

## Mortality at ages 80 and above: cardiovascular diseases predominate

This age group is the only one in which cardiovascular diseases are still the leading cause of death. Decreasing cardiovascular mortality explains most of the decrease in the all-causes rate, accounting for $74 \%$ of female life expectancy gains at age 80 and above between 1990 and 2010, and $62 \%$ of male gains. This pattern explains the gradual convergence with cancer mortality, the second cause of death at this age, which has decreased very slowly in men and virtually stagnated in women due to increasing lung cancer mortality.

Mortality from respiratory diseases has decreased considerably since the late 1990s, thanks to the spread of influenza vaccination, which has had a beneficial effect not only on influenza but also on asthma and other chronic respiratory illnesses. The standardized mortality rate from influenza has fallen from 50 to less than 5 per 100,000 in just 15 years. The mortality rate from asthma, which was only slightly below that of influenza in 1990, has also dropped markedly, decreasing fourfold in 20 years. Respiratory illnesses still ranked third among specific causes of mortality in 2010, however, as they did in 1990, but with a lower standardized rate than the residual category of "other diseases".

Mortality from senile dementias, which has progressively increased over the last 20 years, represents a growing proportion of these "other diseases", accounting for $20 \%$ of male deaths and $27 \%$ of female deaths from "other diseases" in 1990, but $40 \%$ and $50 \%$, respectively, in 2010. The corresponding mortality rate has increased from around 350 to 800 per 100,000 in men and from a little over 400 to 900 per 100,000 in women over the period. Alzheimer's disease, which is responsible for $60 \%$ of deaths attributable to senile dementias, has been rapidly increasing since it was first included in the $9^{\text {th }}$ edition of the International Classification of Diseases, published in 1980. It is difficult, however, to distinguish between the effects of diagnostic improvements - which result from changes in medical and certification practices - and the actual growth in this pathology among the elderly population.

## Life expectancy in good health

A new question now arises. Do the years of life gained in the last 20 years reflect further years in a state of disability or dependence, or a continuous increase in life expectancy in good health? This is a question of particular importance in the contemporary context of population ageing. In recent years there has been a growing literature on the subject, and an ever wider range of
data has been collected with a view to establishing more diverse indicators to capture the phenomenon of disability.

The concept of disability-free life expectancy, without activity limitation or chronic morbidity, was developed in the 1980s (Robine et al., 1986). This indicator is calculated by combining mortality data from vital records and health data from general population surveys. In France, disability-free life expectancy at age 50 increased at the same rate as life expectancy in the 1990s, but more slowly in the following decades. The proportion of years of severe disability, and notably of dependence, has decreased for the cohorts born before the Second World War. There is less clear improvement for the subsequent cohorts, particularly women, for whom the years lived with certain types of severe disability appear to have increased (Cambois et al., 2012). However, it is difficult to determine whether this results from higher survival rates among persons with chronic diseases or disabilities, improved reporting of health problems in surveys, or increased disability in these cohorts in comparison to previous ones. The post-Second World War cohorts also have a higher prevalence of risk behaviours (such as smoking). In addition, the strain of working life may have been greater for women born during the baby-boom years, who have a dual workload in both the workplace and the home (Cambois and Robine, 2012).

## Overview

On 1 January 2014, the population of France totalled 66 million, of which 63.9 million in metropolitan France. Most of the increase in the metropolitan population ( $+270,000$ in 2013) was due to sustained natural growth of $+220,000$, or $0.42 \%$ (although this has slightly slowed since 2006). This growth rate is one of the highest among the countries of the European Union, only half of which have positive natural growth. Net migration is estimated at $+50,000$ in 2013.

The annual number of first residence permits (with a duration of at least one year) remained stable, with 180,000 permits granted in 2012. The majority of recipients were women. Half of these permits were granted for family reasons, and a quarter for educational reasons.

Fertility decreased slightly. Around 780,000 births were registered in 2013, versus 790,000 in 2012. Fertility declined from 2.01 to 1.99 children per woman (1.99 to 1.97 in metropolitan France), and the crude birth rate fell from 12.4 to 12.2 births per 1,000 inhabitants, a decrease of $1.2 \%$ between 2012 and 2013. The rate of increase in mean age at childbearing ( 30.1 in 2013) has slowed; the proportion of fertility at ages 35-39 continues to increase slightly, whereas fertility decreased strongly before age 25 . French fertility remains among the
highest in Europe. For the 1979 cohort, completed fertility is 2.05 children per woman, and mean age at childbearing is 30.1 years.

Abortion figures remained stable in 2012, with little change in the number of induced abortions and the total abortion rate. However, the proportion of first abortions has decreased, whereas the frequency and mean number of repeat abortions has risen. These abortions (all orders combined) occur at a mean age of 27.6.

The downtrend in marriage resumed in 2013 after a slight upturn in 2012, falling to a historical low (in absolute terms) of 231,000 marriages. Marriage was opened to same-sex couples by the law of 17 May 2013, and 7,000 samesex marriages were celebrated in 2013. Civil partnerships (PACS) increased again, with 168,200 PACS concluded in 2013. Since 2011, notaries have been able to perform the registration procedures for PACS unions celebrated in their offices, and $13 \%$ of couples who entered a PACS in 2013 chose this option. More than 50,000 PACS were dissolved in 2013. In cases where this was due to union dissolution ( $60 \%$ of dissolved PACS) and not to the marriage of the partners, it was almost always by mutual consent. Divorces by mutual consent represent half of all divorce applications (out of the 125,000 divorces pronounced in 2013).

A total of 572,000 deaths were registered in 2013, which brings the crude mortality rate to $0.87 \%$. Life expectancy is 85 years for females and 78.7 years for males. This 6.3-year gender difference in life expectancy is slightly lower than in 2012 ( 6.35 years). It reached a maximum of 8.2 years in the early 1990s and has been progressively decreasing since. Improvements in mortality are unequally distributed by sex and age. Due to very low mortality rates below age 30 , the greatest contributions to years of life gained since 1990 have come from decreases above age 45 in men and above age 65 in women. The gains are mainly due to control of cardiovascular diseases and, to a lesser extent, to decreasing male cancer mortality.

## Magali Mazuy, Magali Barbieri, Hippolyte D'Albis • Recent Demographic Trends in France: The Number of Marriages Continues to Decrease

On 1 January 2014, the population of France was 66 million (of which 63.9 million in metropolitan France), an increase of $0.42 \%$ with respect to the previous year. In 2012, 180,000 residence permits were issued to immigrants from countries outside the European Economic Area, a majority of these to women. Half of the permits were issued for family reasons, and a quarter for education. Fertility decreased slightly, to 1.99 children per woman. As the proportion of women of reproductive age in the population also fell and the total population increased, this fertility decline was associated with a decrease in the birth rate in 2013. After a slight increase in 2012, the number of marriages fell once again: according to provisional data, 231,000 marriages were registered in 2013. Marriage was opened to same-sex couples on 17 May 2013, and 7,000 same-sex marriages were registered between May and December 2013. A total of 168,000 PACS (civil unions) were registered in 2013. The number of deaths in 2013 is provisionally estimated at 572,000, and in metropolitan France the number surpassed 560,000. Women's life expectancy was 85.0 years and that of men was 78.7 years, a gap of 6.3 years, down slightly with respect to 2012.

## Magali Mazuy, Magali Barbieri, Hippolyte D’Albis • L’Évolution démographique récente en France : LA DIMINUTION DU NOMbre de mariages se poursuit

Au premier janvier 2014, la France comptait 66 millions d'habitants (dont 63,9 millions en France métropolitaine), soit un accroissement annuel de $4,2 \%$. En 2012, 180000 titres de séjour ont été délivrés à des personnes immigrantes venant de pays tiers. Une majorité de titres concernaient des femmes. Les motifs des titres délivrés relèvent pour moitié de raisons familiales et pour un quart des études. La fécondité diminue légèrement, passant à 1,99 enfant par femme. Cette baisse, conjuguée à la diminution de la part des femmes en âge de procréer au sein de la population et à l'augmentation de la population totale, implique que le taux de natalité est également en baisse en 2013. Après une légère remontée en 2012, le nombre de mariages diminue à nouveau : d'après les données provisoires, on a enregistré 231000 mariages en 2013. Le mariage a été ouvert aux couples de même sexe le 17 mai 2013 et 7000 mariages ont été enregistrés entre mai et décembre 2013. Le nombre de pacs enregistrés en 2013 est de 168000. Le nombre de décès en 2013 est provisoirement estimé à 572000 , et en France métropolitaine, il dépasse le seuil de 560000 . L'espérance de vie des femmes est de 85 ans et celle des hommes de 78,7 ans, soit un écart de 6,3 ans en légère diminution par rapport à l'année 2012.

## Magali Mazuy, Magali Barbieri, Hippolyte d'Albis • LA Evolución demográfica reciente en Francia: la diminución del número de matrimonios continua

El primero de enero de 2014, Francia contaba con 66 millones de habitantes (de los cuales 63,9 millones en Francia metropolitana), o sea un crecimiento anual de 4,2 p. 1000. En 2012, 180000 permisos de residencia han sido otorgados a personas inmigrantes en proveniencia del exterior de la Unión Europea. Una mayoría de permisos concernían mujeres; la mitad de los títulos correspondían a motivos familiares y un cuarto a estudios. La fecundidad disminuye ligeramente en 2013 y pasa a 1,99 hijos por mujer. Esta baja, conyugada con la disminución del número de mujeres en edad de procrear y el aumento de la población total, ha conducido igualmente a una baja de la tasa de natalidad. Después de un ligero aumento en 2012, el número de matrimonios disminuye de nuevo: según los datos provisionales de 2013, se han registrado 231000 matrimonios. Los matrimonios de parejas del mismo sexo, autorizados desde el 17 de mayo de 2013, suman un total de 7000 matrimonios entre esa fecha y el 31 de diciembre del mismo año. El número de Pacs (Pacto civil de solidaridad) en 2013 ha alcanzado 168000. Según los datos provisionales, el número de muertes en 2013 es de 572000, sobrepasando 560000 en Francia metropolitana. La esperanza de vida de las mujeres es de 85 años y la de los hombres de 78,7 años, es decir una diferencia de 6,3 años, ligeramente más baja que en 2012.

Keywords: France, demographic situation, ageing, migration, fertility, marriage, mortality, causes of death.

Translated by Paul Reeve.

[^0]:    (1) These are provisional data published by INSEE (Bellamy and Beaumel, 2014). Net migration has been estimated at $+50,000$. The figure has been adjusted slightly downward since 2010.
    (2) Appendix Tables A. 1 to A. 16 are given at the end of the article. They are updated annually with the latest available data. The table numbers do not always correspond to the order in which they are cited in the text.

[^1]:    (3) Croatia joined the European Union on 1 July 2013. It has a population of 4,246,700. The estimated population of the European Union on 1 January 2014 was 507.4 million.

[^2]:    1 Shortfall of births due to the war of 1870
    2 Exceptional infant mortality in 1911 due to a summer heat wave
    3 Military losses of the 1914-1918 war
    4 Shortfall of births due to the 1914-1918 war (depleted cohorts)
    5 Depleted cohorts reach childbearing age
    $\begin{array}{ll}6 & \text { Shortfall of births due to the war of 1939-1945 Coverage: Metropolitan France. } \\ 7 & \text { Start of baby boom }\end{array}$
    7 Start of baby boom
    8 End of baby-boom

[^3]:    (5) Countries whose nationals no longer require a residence permit: member countries of the European Union on 30 June 2014, as well as Vatican City State, Iceland, Liechtenstein, Norway, the principalities of Andorra and Monaco, the Republic of San Marina and Switzerland.

[^4]:    (6) Appendix Table A. 7 has not been updated with data from very recent years because Eurostat no longer publishes series of age-specific rates that would allow us to calculate longitudinal indicators. The disparities between countries may have increased in certain cases.
    (7) From 2010, the data include induced abortions covered by specific health insurance funds for the self-employed and farmers, the Régime social des indépendants (RSI) and the Mutuelle sociale agricole (MSA). A total of 1,531 procedures were recorded in metropolitan France (Vilain and Mouquet, 2014).

[^5]:    (8) Mean age based on age-specific rates, calculated for all induced abortions, applying the age distribution drawn from the PMSI (supplied by DREES). The database drawn from the 2012 abortion notifications is in preparation and is not available at the time of writing, so has not been used.

[^6]:    (9) Partners who register a PACS are exempt from inheritance taxes, but the surviving partner does not inherit the deceased partner's property unless a will is drawn up.

[^7]:    (10) The most recent three-year life table is the one produced by INSEE for the years 2010-2012. However, as statistics on death by cause are not yet available for 2012, the analysis of mortality by cause can only be carried up to the year 2011.

[^8]:    (11) For the sake of simplicity we will refer to 1990 and 2010 when describing results from the threeyear life tables for 1989-1991 and 2009-2011.

[^9]:    (12) According to INPES analyses (http://www.inpes.sante.fr/10000/themes/tabac/consommation/ profils-fumeurs.asp, site consulted on 4 September 2014).

[^10]:    * Provisional.
